# How good is the IMO Working List of Meteor showers? A complete analysis of the IMO Video Meteor Database <br> Sirko Molau, Abenstalstr. 13b, 84072 Seysdorf, Germany 

## Motivation

Since the start of the AKM network in 1999, which was renamed to IMO Video Meteor Network in 2004, plenty of single-station video data have been collected by numerous video observers. As of today, the database has grown to more than 200,000 meteor records. Until now, however, detailed analyses have only been carried out for selected meteor showers like the Perseids (Arlt, 2003) and the Taurids (Triglav-Cekada and Arlt, 2005). Most showers remained unanalysed. Short-term meteor shower outbursts were recorded, but so far they were only noticed if an observer got aware of them by chance (c.f. the October-Carmelopardalid outburst of October 5, 2005).

When the video network was established, the central aim was to cover the annual meteor shower activity within three to five years completely. This goal has been achieved at large. Since we now have the observational basis, it was time for a first complete analysis of meteor shower activity based on the video meteor database.

## Theoretical background

Searching for meteor showers in a set of meteor records comes down to a pattern recognition problem. The basic formula for all statistical pattern recognition system is Bayes' decision rule:

$$
R=\underset{R^{`}}{\operatorname{argmax}} P\left(R^{‘} \mid M\right)
$$

Bayes‘ rules states, that given a set of observations M (in this case: meteors), you should choose the set of classes R (in this case: radiants) such that the a-posteriori (or posterior) probability $\mathrm{P}(\mathrm{R} \mid \mathrm{M})$ is maximized. Applying Bayes' rule guarantees minimum classification errors.

Unfortunately, the a-posteriori probability distribution $\mathrm{P}(\mathrm{R} \mid \mathrm{M})$ is usually unknown and difficult to model, which is why it is often transformed according to Bayes‘ Identity:

$$
\mathrm{P}(\mathrm{R} \mid \mathrm{M})=\frac{\mathrm{P}(\mathrm{R}) * \mathrm{P}(\mathrm{M} \mid \mathrm{R})}{\mathrm{P}(\mathrm{M})}
$$

Hereby, $P(M \mid R)$ is the class-conditional probability distribution, and $P(R)$ and $P(M)$ are the a-priori (or prior) probability distributions. Hence, we can write the classification problem as:

$$
\mathrm{R}=\underset{\mathrm{R}^{`}}{\operatorname{argmax}} \frac{\mathrm{P}\left(\mathrm{R}^{`}\right) * \mathrm{P}\left(\mathrm{M} \mid \mathrm{R}^{`}\right)}{\mathrm{P}(\mathrm{M})}
$$

The conditional probability distribution $\mathrm{P}(\mathrm{M} \mid \mathrm{R})$, i.e. the probability that a meteor belongs to a given radiant, can be modeled easily. It is equivalent to the standard criterion for meteor shower assignment in visual observation, which is based on the radiant altitude, the distance of the meteor's backward prolongation from the radiant, the meteor velocity and the meteor length relative to the distance from the radiant (c.f. the chapter on shower association in the IMO handbook for visual observers, Rendtel et al, 1995). A closed-form analytical solution for the optimization problem is not obvious, so often iterative algorithms like Expectation Maximization (EM algorithm) are applied. A more simple
approach is a full search over all possible radiants, selecting those, which fit to at least a pre-defined minimum number of meteors.

The a-priori probability distribution of radiants $\mathrm{P}(\mathrm{R})$ can be modeled as well. This factor captures prior knowledge about meteor showers like the fact, that radiants near the ecliptic are more probable than radiants at large ecliptical latitudes, and that meteors from radiants below the horizon of the observer are impossible. In the most simple case, $\mathrm{P}(\mathrm{R})$ is assumed to be equally distributed (i.e. all radiants have the same probability) and becomes a constant factor in the optimization problem that can be neglected.

The probability of the observation $P(M)$ is a constant factor that can be neglected as well. Hence, detecting meteor showers comes down to finding radiants that maximize the class-conditional probability $P(M \mid R)$.

A radiant is defined by a four-dimensional vector composed of the right ascension $\alpha$ and declination $\delta$, the pre-atmospheric velocity $\mathrm{v}_{\infty}$ and solar longitude $\lambda$ (equivalent to the time of year). During the optimization, the probabilities $P(M \mid R)$ are accumulated over all meteors and all possible radiants with high resolution (i.e. small step size) in all four axes. A meteor showers radiant will manifest itself as a local probability maximum in the four dimensional space, and a meteor shower active over some period of time will cause a probability maximum which is elongated along the solar longitude axis.

## Practical aspects of the implementation

Searching for elongated local maxima in a four dimensional space is not straight forward. A fourdimensional Hough transform may be applied, but the computation would be tricky and memory demanding. A possible approximation is to accumulate the probabilities $P(M \mid R)$ at first for short solar longitude intervals independently, reducing the probability space to three dimensions (right ascension, declination, velocity). This part of the calculation, which is carried out by the RadFind tool, is similar to run Rainer Arlts Radiant software (Arlt, 1992) for all possible meteor shower velocities at once.

In a second step, probability maxima (radiants) are determined for each solar longitude interval. The search is straight forward, since the software simply needs to search for local peaks in the threedimensional probability distribution.

Meteor showers are determined in a third step by looking for radiants with similar parameters (right ascension, declination, velocity) in consecutive solar longitude intervals. This search is implemented in the StrmFind tool. In addition, StrmFind tries to identify detected meteor showers using IMO‘s Working List of Meteor Showers and a set of known sporadic sources.

## Detecting radiants with RadFind

The class-conditional probability distribution $\mathrm{P}(\mathrm{M} \mid \mathrm{R})$ was modeled by a two-dimensional Gaussian distribution:

$$
\mathrm{P}(\mathrm{M} \mid \mathrm{R})=\frac{\exp \left(-0.5 \mathrm{D}^{2}\right) * \exp \left(-1.5 \mathrm{~V}^{2}\right)}{\mathrm{N}}
$$

Here, D denotes the miss distance between the backward prolongated meteor and the radiant in degree, and V the difference between the expected and the observed apparent meteor velocity in degree per second. The expected angular velocity was computed by the refined equation of Gural (1999). P (M I R ) is set to zero for radiants below the horizon, or when the meteor did not fit to the radiant for other reasons (too long, moving towards the radiants). The scaling factors 0.5 and 1.5 were set empirically.

The norm factor N is necessary to make sure that each meteor contributes the same unity probability mass, which is required by probability theory. From the analysis of visual observations with the Radiant software it is known, however, that short meteors close to a radiant are strongly overweighted. Their probability mass is distributed over a few radiant bins only, whereas the probability mass of long meteors at larger radiant distances is shared by many radiant bins leaving only little probability mass for each. In fact, too slow meteors are often omitted in these analyses. For this reason, the norm factor N was neglected here, resulting in unnormalized distributions and more weight for long meteors.

Another problem arises from the imperfect meteor distribution around the radiant and the discrete sampling of radiant positions and velocities. A given meteor may cause more than one local probability maximum as depicted in Figure 1. Furthermore, strong meteor showers may mask weaker ones when their probability distributions overlap (Figure 2).

Figure 1: The backward prolongation of one or more meteors (black line) may result in several local maxima in the discrete probability space (rectangles with different shades of grey)

Figure 2: Overlapping probability distributions of two showers (dotted lines) may cause that the weaker shower is masked by the stronger (thick line).

Both problems are solved by applying an iterative algorithm. It extracts not all radiants at a time, but in each iteration only the strongest, which is subsequently removed from the data set:

- compute the global probability distribution $P(M \mid R)$ over all meteors
- loop
- determine the strongest radiant $\mathrm{R}_{\mathrm{G}}$ belonging to global maximum of the probability distribution

$$
\mathrm{R}_{\mathrm{G}}=\underset{\mathrm{R}^{`}}{\operatorname{argmax}} \mathrm{P}\left(\mathrm{M} \mid \mathrm{R}^{`}\right)
$$

- determine the subset of meteors $\mathrm{M}_{\mathrm{G}}$ belonging to the radiant $\mathrm{R}_{\mathrm{G}}$ using the standard criteria for meteor shower association
- compute the probability distribution $\mathrm{P}_{\mathrm{G}}\left(\mathrm{M}_{\mathrm{G}} \mid \mathrm{R}\right)$ over the meteor subset
- determine the final parameters of the strongest radiant from the meteor subset $\mathrm{M}_{\mathrm{G}}$

$$
\mathrm{R}_{\mathrm{G}}=\underset{\mathrm{R}^{`}}{\operatorname{argmax}} \mathrm{P}_{\mathrm{G}}\left(\mathrm{M}_{\mathrm{G}} \mid \mathrm{R}^{\prime}\right)
$$

- subtract the probability distribution $\mathrm{P}_{\mathrm{G}}\left(\mathrm{M}_{\mathrm{G}} \mid \mathrm{R}\right)$ from the overall distribution $\mathrm{P}(\mathrm{M} \mid \mathrm{R})$ and repeat the analysis for the next strongest radiant

In the example of Figure 2, the contribution of the strong radiant (large Gaussian) is removed from the overall distrubution after the first iteration, leaving only the contribution of the weak radiant (small Gaussian).

To estimate the activity of a given radiant from the available data is not straight forward. The plain number of meteor alone is a poor estimate, since the effective observing time varies significantly from one solar longitude interval to the next. The meteor number belonging to a radiant relative the overall number of meteors in this solar longitude interval is better estimate. Still it is heavily affected by other radiants. The Taurid activity profile, for example, would have a major gap during the Leonid maximum.

Therefore, the following approach was choosen: At first, all active radiants and meteors belonging to these radiants are determined. The remaining meteors are assumed to be the sporadic background, which should vary only little within a few days or weeks. The activity index of a given radiant is then defined as the ratio of the number of meteors belonging to the radiant, and the meteor number from the sporadic background. It turns out, that this measure results in accurate qualitative profiles of the meteor shower activity over time. However, it cannot be used to compare the strength of two showers, as a meteor shower that is active all night with the radiant high in the sky will have a stronger profile than a shower whose radiant rises just before dawn. To account for this effect, each meteor would need to be weighted with $\sin ^{-1}$ of the radiant altitude at its appearance time.

There is one case, where the activity measure in connection with the iterative radiant determination is problematic: If there are two nearby radiants with approximately the same strength like the Taurids, their activity measures with interfere: At first, the Southern Taurids show the stronger radiant. Hence, they will be extracted first from the data set, and all meteors radiating from in between the southern and northern branch will be counted as Southern Taurids. At some points, the Northern Taurids become more prominent. Now, the northern branch is extracted first and intermediate meteors are assigned to it. This explains, why between 221 and 226 degree solar longitude, the activity of these two showers seems to jump erratically.

To account for this side effect would require to repeat the meteor shower assignment for each meteor once all showers are extracted from the data set.

For the analysis presented in this paper, the following parameter setting were used:

- 360 overlapping solar longitude intervals ( $2^{\circ}$ interval length, $1^{\circ}$ shift)
- $1 / 2^{\circ}$ step size in right ascension and declination
- $1 \mathrm{~km} / \mathrm{s}$ step size in velocity

With these settings, the radiant search comes down to computing about $2 \times 2 \times 2.5$ Million radiant probabilities for each of the almost 200,000 meteors in the database (one factor of two results from the iterative algorithm, the other from the overlapping solar longitude intervals). The calculation took about one month on two HP DL-380 Win 2003 servers with two 3 GHz dual-core CPUs each.

## Detecting meteor showers with StrmFind

The output of the RadFind tool is a set of radiants for each solar longitude interval. To detect meteor showers that are active over a longer period of time, it is necessary to search subsequent solar longitude
intervals for radiants with similar parameters. In this analysis, maximum deviations of $7^{\circ}$ in the radiant position and $7 \mathrm{~km} / \mathrm{s}$ in velocity were allowed for subsequent solar longitude intervals. To be reported, a meteor shower needed to be detected in at least six subsequent solar longitude intervals (all empirical values).

From the individual radiants, mean radiant position and velocity values as well as the radiant drift were determined for each shower. Then, the detected meteor showers were matched against the IMO Working List and six known sporadic sources (N/S Apex, N/S Toroidal, Helion, Anthelion). Here, at most $15^{\circ}$ position and $15 \mathrm{~km} / \mathrm{s}$ velocity deviation were accepted.
It turned out, that the number of detected meteor showers depends strongly on the parameter set. By slightly relaxing the criteria, hundreds of "meteor showers" can be „generated". To keep the list short and concentrate on the most probable showers, slighter tighter criteria than given above were applied to showers that neither belonged to the IMO Working List nor to one of the sporadic sources.

Since meteor showers have a fixed velocity, it might be useful to recompute the radiant position in the individual solar longitude intervals with the fixed mean velocity. However, this requires that the same subset of meteors is used that was assigned to the radiant before. Otherwise meteors from other showers with different velocities may strongly dilute the radiant, as they will not converge anymore at their proper radiant position.

Figures 3 and 4 show the differences in radiant position of the Perseids with and without fixed velocity. As the differences are only marginal, the position correction was not applied in the analysis presented here.

Figure 3: Radiant position of the Perseids (upper graph) when the best velocity fit for each solar longitude interval is used (lower graph).

## Results

The results presented in this section are based on a total of 188,068 meteors records collected in 2,146 observing nights and more than 42,500 hours effective observing time between January 1993 and February 2006. Table 1 lists all observers that contributed more than thousand video meteor records.

Table 1: Video observers, who contributed most data to the analysis presented here.

| Observer | Country | Obs. Nights | eff. Obs. Time [h] | Meteors |
| :--- | :---: | :---: | :---: | :---: |
| Sirko Molau | Germany | 1287 | 9354,0 | 64011 |

Figure 5 shows the distribution of meteors over solar longitude. As expected, most meteor records come from the second half of the year. In addition, there are strong peaks caused by the Perseids, Leonids, and Geminids. The number of meteors varies between 200 (March 7 / solar longitude $348^{\circ}$ ) and 13,021 meteors (November 19 / solar longitude $236^{\circ}$ ) per interval.

Figure 5: Distribution of meteors over solar longitude.

With the settings described above, 54 meteor shower were found. 24 of these were known showers from the recently updated IMO Working List (Arlt and Rendtel, 2006), among them the Antihelion source, which can be detected numerous times in the course of the year. Four sporadic sources could be identified, and the remaining 26 showers did neither fit to the IMO Working List nor to any sporadic source.

Table 2 gives the details of the detected meteor showers, ordered by their appearance date. The columns are as follows:

- ID - arbitrary identifier from the detection algorithm
- Period of Activity - solar longitude interval in which a radiant was detected, the corresponding dates, and the overall number of meteors belonging to the shower (in parenthesis are the reference values from the IMO Working List, if available).
Beware that the given meteor number is about two times the real number of meteors, since due to the overlapping solar longitude intervals most meteors were counted twice.
- Maximum Activity - solar longitude and date of maximum activity, maximum activity index (in parenthesis are the reference values from the IMO Working List, if available).
- Properties - right ascension, declination, and velocity of the meteor showers at the time of maximum activity (in parenthesis are the reference values from the IMO Working List and for the sporadic source at the observed time of maximum activity, if available)
- Drift - average drift in right ascension and declination per day (in parenthesis are the reference values from the IMO Working List or for the sporadic source, if available). Beware that the radiant position in solar longitude intervals with low activity is difficult to determine, which is why the drift values may contain large errors.
- Remarks - name of the shower or sporadic source, if known, and further comments

Figure 6 contains activity graphs for all showers from the IMO working list, and a number of other interesting showers. Please note, that the scale of the $y$-axis varies for strong showers.

Table 2: List of detected meteor showers.

| ID | Period of Activity |  |  | Maximum Activity |  | Properties |  |  |  | Drift |  | Remark |  |

Remarks:
${ }^{1}$ much longer activity interval than in the IMO Working List
${ }^{2}$ similar to the radiant of COM
${ }_{4}^{3}$ narrow radiant, well-shaped activity profile
${ }_{5}^{4}$ no clear activity profile, almost constant activity
${ }_{6}^{5}$ no clear activity profile
${ }^{6}$ relative compact radiant at high declination, conspiciously slow, no clear activity profile
${ }_{8}^{7}$ remarkably strong activity with a clear peak
${ }^{8}$ asymmetric profile: steep ascending, shallow descending branch; significantly shorter activity interval than in the IMO Working List ${ }^{9}$ remarkably strong activity with a clear peak
${ }^{10}$ noticable activity only at $92^{\circ}$ solar longitude, radiant more than $10^{\circ}$ north of the expected position
${ }^{11}$ almost constant, relatively strong activity
${ }_{13}^{12}$ probably the ascending branch of shower 24
${ }^{13}$ almost no ascending, but slow descending branch
${ }_{15}^{14}$ early part of the Perseids
${ }_{16}^{15}$ probably the descending branch of shower 19
${ }^{16}$ the only clear shower from the Aquarid complex, activity possibly ends at $145^{\circ}$ solar longitude
${ }^{17}$ well-known extremely long ascending branch with activity plateau at $134-137^{\circ}$ solar longitude
${ }^{18}$ similar to the radiant of CAP
${ }^{19}$ similar to the radiant of PER
${ }^{20}$ much larger radiant drift than in the IMO Working List
${ }^{21}$ conspiciously slow, no clear activity profile
${ }^{22}$ no clear activity profile
${ }^{23}$ very short activity interval, radiant far from the expected position
${ }_{25}^{24}$ weak radiant close to the north equatorial pole
${ }^{25}$ strong radiant more than $10^{\circ}$ south-west of the expected position
${ }^{26}$ until $220-225^{\circ}$ solar longitude stronger than NTA
${ }^{27}$ early branch of NTA
${ }^{28}$ almost perfect Gaussian activity profile
${ }_{30}^{29}$ significantly earlier active than in the IMO Working List
${ }^{30}$ related to October-Camelopardalids?
${ }^{31}$ no clear activity profile, radiant far east from the expected position
${ }_{32}^{32}$ starting from 220-225 ${ }^{\circ}$ solar longitude stronger than STA
${ }^{33}$ similar to the radiant of ORI
${ }^{34}$ similar to the radiant of STA
${ }_{36}^{35}$ conspiciously slow, almost constant activity
${ }^{36}$ strong peak and weak background component
${ }^{37}$ similar to the radiant of NTA
${ }^{38}$ well-defined radiant motion just as expected, but $10^{\circ}$ northwest of the expected position
${ }^{39}$ activity possibly ends at $266^{\circ}$ solar longitude
${ }^{40}$ activity interval much longer than in the IMO Workling List,
asymmetric profile with shallow ascending and step descending branch
${ }^{41}$ well-defined radiant at the expected position, but more than one month behind in time
${ }^{42}$ ascending branch missing
${ }^{43}$ similar to the radiant of COM

## Final remarks

Three meteor showers from the IMO Working List with declinations larger than $-20^{\circ}$ were not found, namely the delta Leonids, Draconids, and alpha Monocerotids. The latter two can be explained easily they did not meet the minimum duration criterion in the meteor shower search. In fact, the JuneBootids, Aurigids, and Ursids did not meet this criterion either, but they clearly showed up when the number was reduced to five solar longitude intervals. For this reason, they were added to the shower list (Table 2).

With about 15,000 meteor records from two Australian observers, the data set for the southern hemisphere makes up for less than ten percent of the whole database. Still, it is remarkable that beside the Antihelion and Apex Source not even a single meteor shower with a declination below $-20^{\circ}$ was found.

Only one of the detected shower had a velocity greater than $65 \mathrm{~km} / \mathrm{s}$. Figure 7 shows the distribution of the computed vs. the expected velocity for known showers. The solid line depicts equal values. It is obvious, that the velocity is systematically underestimated for fast meteor showers. The reason for that deviation is not yet known.

Figure 7: Observed vs. expected velocity for known meteor showers.

## Conclusions

The new IMO Working List of Meteor Showers presented by Arlt and Rendtel (2006) is largely confirmed by this analysis. However, a number of significant discrepancies (e.g. KCG, AUR, COM and MON) need to be sorted out and corrections (especially with respect to the activity interval and radiant position of meteor showers) should take place. Many of the unknown showers presented in this analysis will be detectable by visual observers and should become the target of further investigation.

The analysis procedure presented here proved to be useful for detecting meteor showers that are active for at least a week. The software can be used to detect short-term meteor outburst, too, but that will require tighter filter criteria to discerne between real showers and statistical fluctuations.

Even though single-station video observations have certain limits compared to double and multi-station observations, they have proven to be useful for meteor shower analysis. Since they are easier to obtain, single station data outnumber the other by far, which makes them especially useful for the determination of activity profiles.
