

Results of the IMO Video Meteor Network – February 2017

Sirko Molau, Abenstalstr. 13b, 84072 Seysdorf

2017/08/02

75 video cameras contributed to the IMO network in February 2017. They recorded about 14,000 meteors in 7,000 hours of effective observing time. The monthly statistics reveal large gaps and so the output was below the average of the last five years. The bandwidth of this month reached from less than a hundred meteors in the night of February 11/12 up to more than a thousand meteors per night at the middle of February. With an average of 2.0 meteors per hour we approach the annual activity low.

Since there are no noteworthy meteor shower in February, we focused on a set of minor showers close to the detection limit. Specifically, we analyzed six meteor showers in detail which we detected in the IMO network data during our 2012/2013 analysis. Which activity profile will we get now that we collected continuous flux density measurements over six years? The answer will be given by the following figures.

The alpha Coronae Borealis (429 ACB) are active beyond the boundary between January and February. Overall, we recorded 1,500 shower members between January 26 and February 4 at an effective collection area of 830,000 km² and hour. For comparison: At the same time, we observed 9,000 sporadic and 3,000 Anthelion meteors. The mean profile (Figure 1) shows a constant level of activity with a flux density of 2 meteoroids per 1,000 km² and hour. The activity profiles of the individual years do not differ significantly from the average.

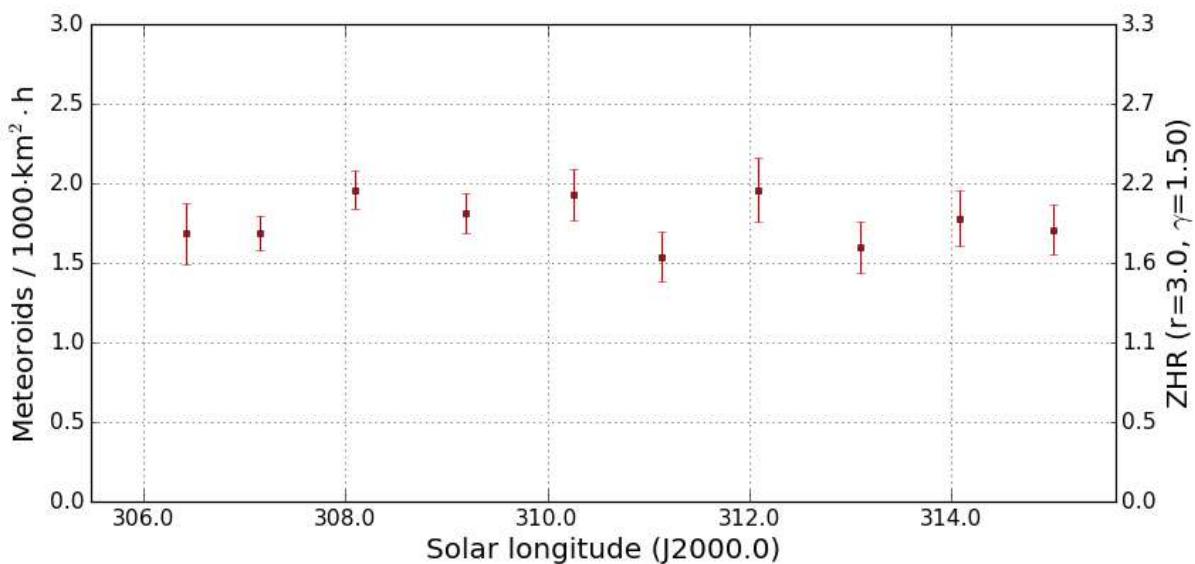

Figure 1: Average flux density profile of the alpha Coronae Borealis in the years 2012 to 2017, derived from video data of the IMO Network.

The activity period of the February epsilon Virginids (506 FEV) reaches from January 28 to February 8. 1,700 shower members (12,000 SPO / 3,600 ANT) were recorded at this time with an effective collection area of more than 1.3 million km² and hour. Also here we find a smooth activity profile without a clear peak (figure 2), but the absolute flux density level is lower than before. The individual annual profiles do not provide additional information.

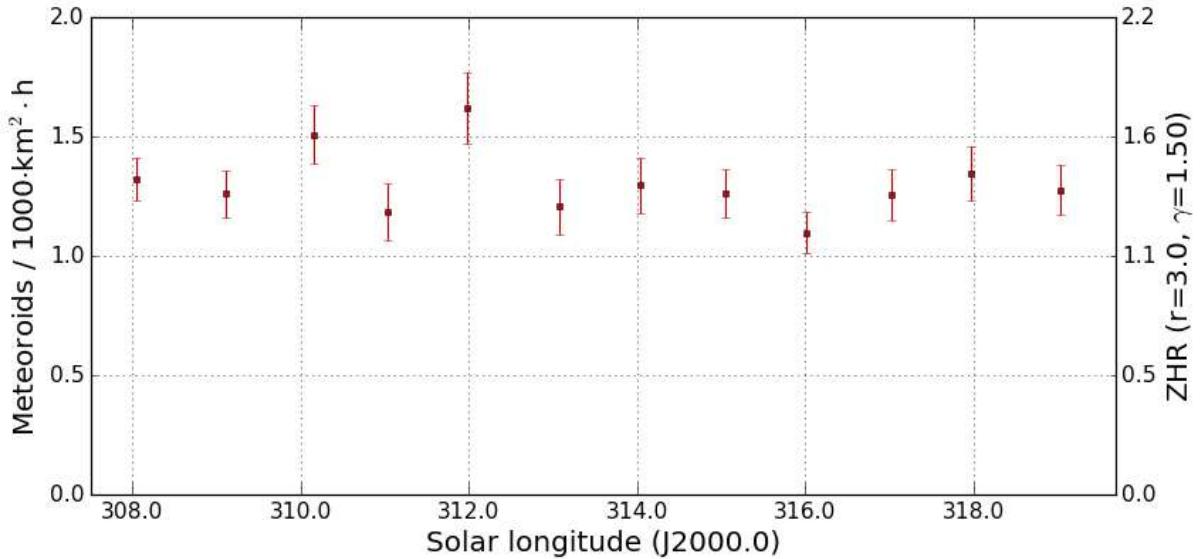

Figure 2: Average flux density profile of the February epsilon Virginids in the years 2012 to 2017, derived from video data of the IMO Network.

In parallel, but with a shorter activity window, we find the February eta Draconids (427 FED). The shower is detectable between February 2 and 5 and provides the smallest flux density of all showers analyzed here, but it is the only one with a classical activity profile (figure 3). Thanks to the circumpolar radiant we obtained a remarkable effective collection area of 880,000 km² and hour despite the short activity interval. Overall 400 shower members (4,000 SPO / 1,200 ANT) were recorded. Peak activity is reached at 315.2° solar longitude (February 3, 2017, at 2:00 UT). A look at the individual years reveals that the 2013 peak was particularly prominent.

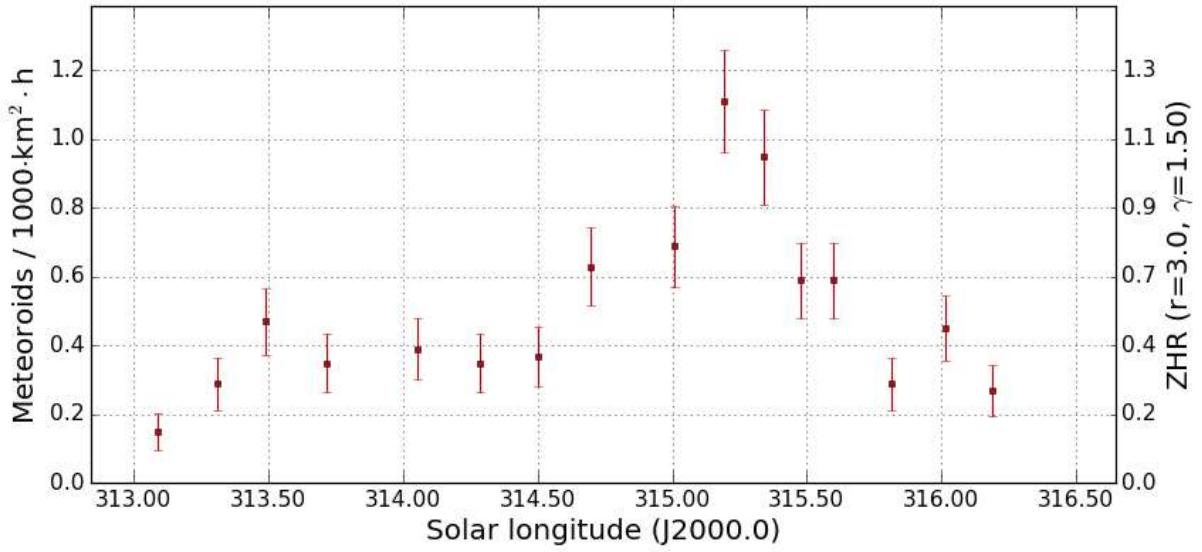

Figure 3: Average flux density profile of the February eta Draconids in the years 2012 to 2017, derived from video data of the IMO Network.

The minor shower of the pi Hydrids (101 PIH) is active between February 3 and 9. Despite the effective collection area of only 180,000 km² and hour we assigned 650 meteors to that radiant (7,000 SPO / 2,100 ANT). Indeed, the flux density reaches larger values of almost 4 meteoroids per 1,000 km² and hour. There are no outliers in the individual years.

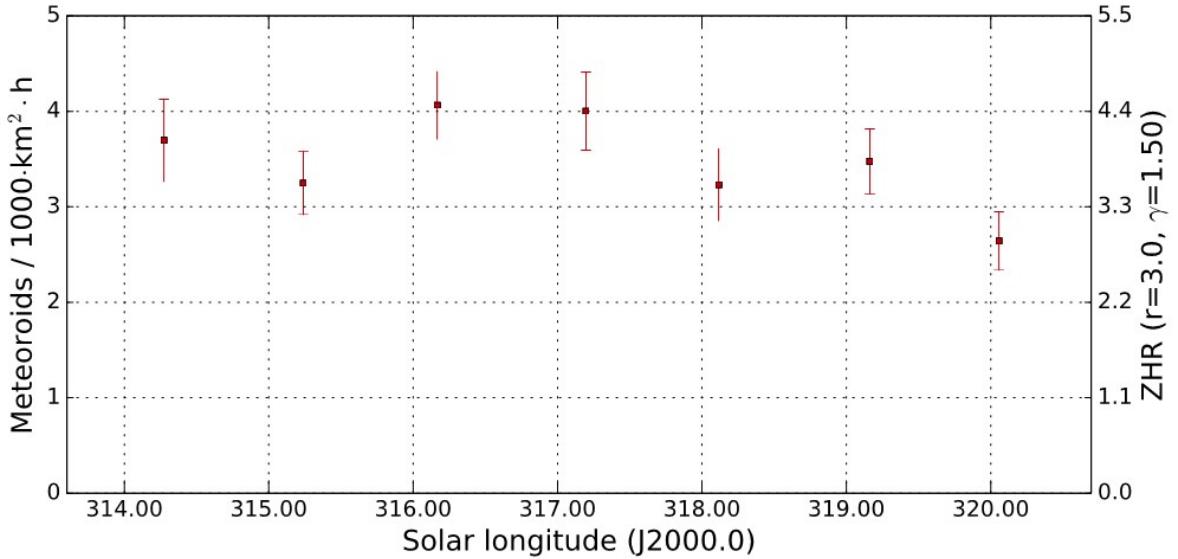

Figure 4: Average flux density profile of the *pi* Hydrids in the years 2012 to 2017, derived from video data of the IMO Network.

In the middle of February, we find the beta Herculids (418 BHE). We recorded 700 shower members (5,000 SPO / 1,700 ANT) with an effective collection area of 700,000 km² and hour between February 12 and 16. The flux density level is constant at a level of 1 meteoroid per 1,000 km² and hour (figure 5) and there are no significant deviations in individual years.

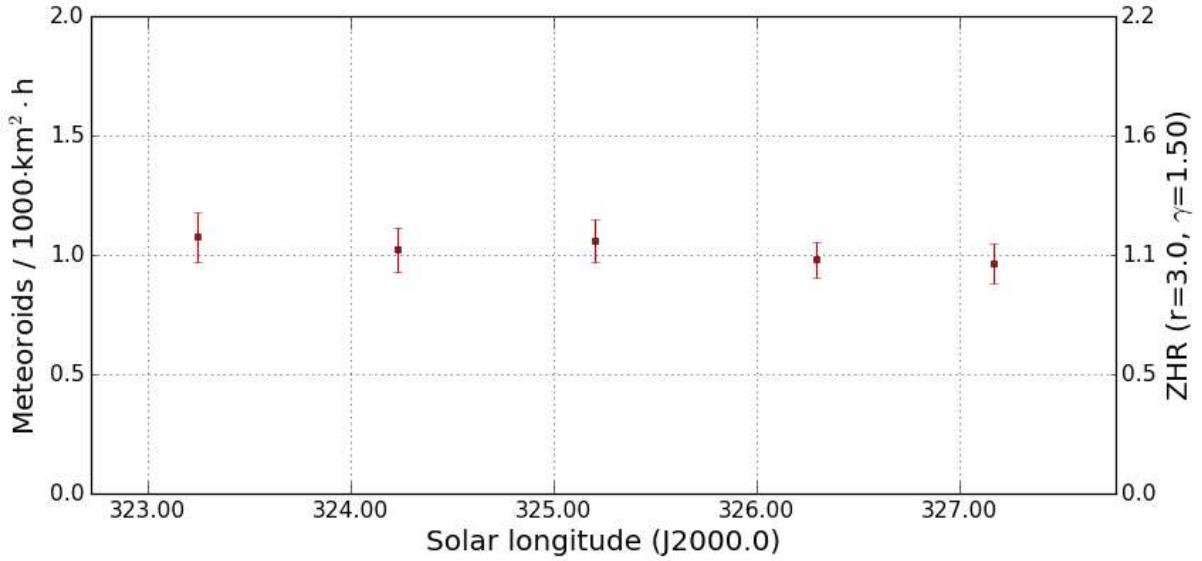

Figure 5: Average flux density profile of the beta Herculids in the years 2012 to 2017, derived from video data of the IMO Network.

Last but not least we obtained data from 2,000 February mu Virginids (516 FMV) from February 14 to 28 (14,000 SPO / 4,800 ANT). The collection area of the IMO network summed up to nearly a million km² and hour. The activity profile shows only small variations as in the other cases before (figure 6) and the flux density scatters around a value of 2.

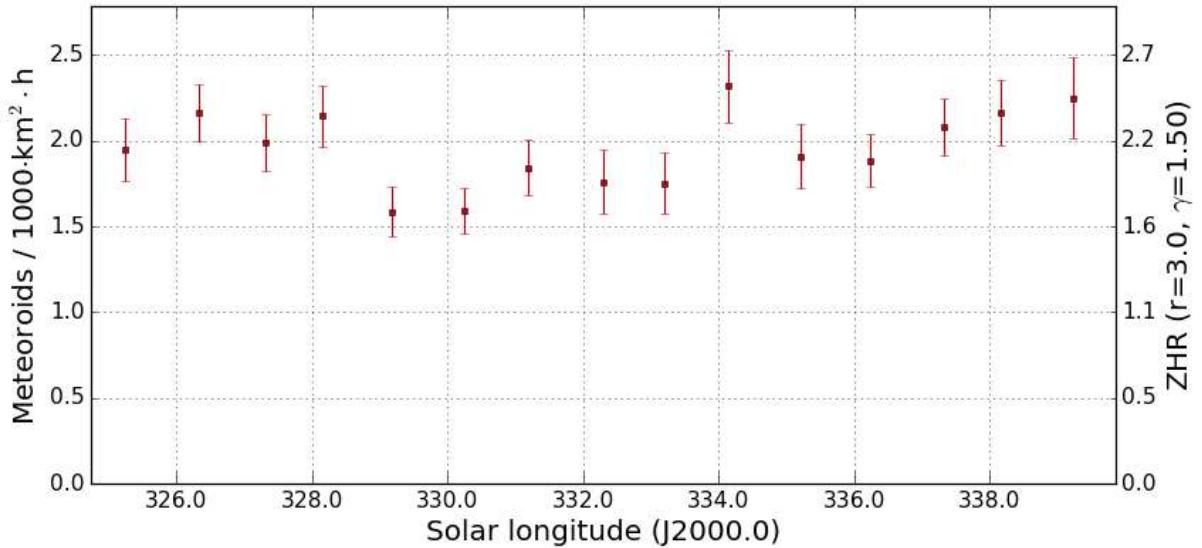

Figure 6: Average flux density profile of the February mu Virginids in the years 2012 to 2017, derived from video data of the IMO Network.

Looking at the profiles of the individual years we find indeed an outlier on February 18/19, 2014, at which the flux density was by a factor 4 to 5 higher than usual (figure 7). In detail this peak is made up of ten shower members which were recorded in a night with a particularly small effective collection area. In fact, we can even further pin down the outlier to five shower meteors recorded by all active video network cameras between 2 and 4 UT. So we can assume that this outlier is of statistical nature only.

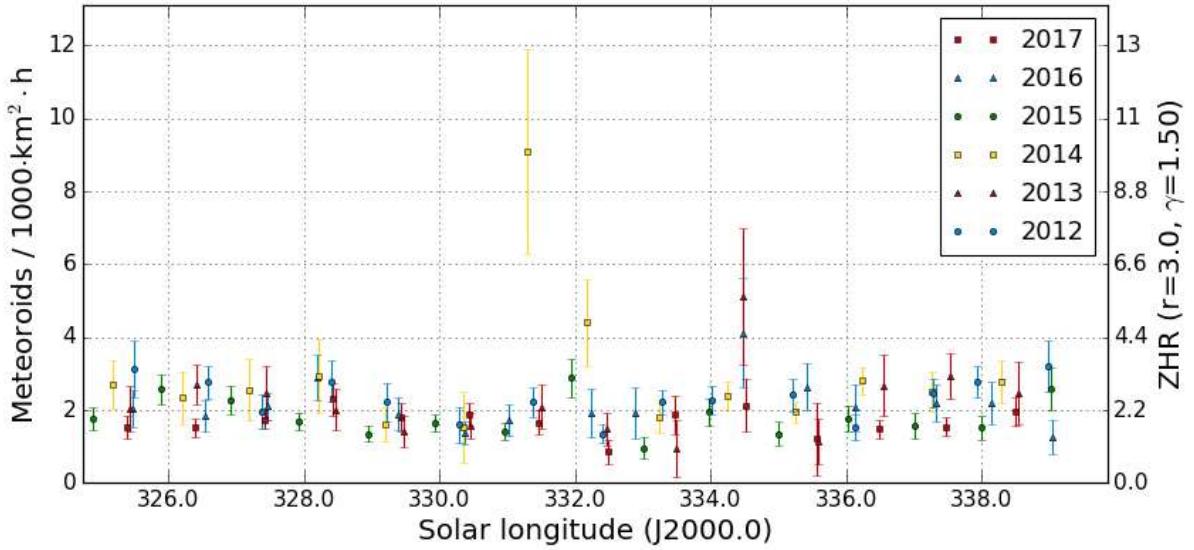

Figure 7: Individual profiles of the February mu Virginids in the years 2012 to 2017.

In summary we can conclude that no February source stands clearly out of the background. Only the February eta Draconids provide a classical activity profile with a peak on February 2/3. In this case, our video cameras are particularly effective data collectors thanks to the favorable location of the radiant and the low meteor shower velocity.
